

What is an example of an input to a C compiler that would cause a lexical analysis error?

What is an example of an input to a C compiler that would cause a syntactic analysis error?

Project 1

- Out tonight
- Add Flex rules for our language
- Might want to find a project partner!

What should we call our language?

- Flipped Wednesdays?

KU | EECS 665 | Drew Davidson

CONSTRUCTION

2 – Implementing Scanners

Compiler Construction Progress Pics

Currently working on lexical analysis concepts

 Convert the character stream from the user into the token stream (the "words" of the programming language)

From lexical definition to lexical recognition

Why the Regex Makes a Good Lexical Specification

Closed under...

- Concatenation
- Union
- Repetition
- Complementation
- ...and more!

Equivalent to DFAs

This matters for implementation!

DFAs: Easy to Implement RegEx Properties

DFA (Graph Depiction)

DFA (Successor Notation)

<Current state>,<Transition symbol> = <next state>

S,x = A

A,x = D

$$A,y = D$$

DFA (Array Implementation)

Row: current state Column: transition symbol Cell: next state

Walk through the translation process formally

Use an *expression tree*:

- Leaf: atomic operand
- Branch: operations joining subtrees

Expression Tree Examples

Thompson's Construction Intuition Thompson's Construction Algorithm

Two-Step Process:

- Break the RegEx down to the simplest units with "obvious" FSMs (i.e. expression tree leaves)
- Combine the sub-FSMs according to operator rules (i.e. expression tree branch rules)

Recombobulate the Regex into an FSM piecewise

Thompson's Construction Alg. Build the RegEx Tree | Replace nodes bottom-up

Concatenation:

Concatenation:

Thompson's Construction Alg. Build the RegEx Tree | Replace nodes bottom-up

 $(a|\varepsilon)(c|d|b)^*$

Thompson's Construction: Side-Note Build the RegEx Tree | Replace nodes bottom-up

The FSMs produced by Thompsons Construction are a little bit messy!

- Clearly less efficient than what we would do by hand
- Designed for ease of proofs
- In practice, it's easy to minimize FSMs later

From RegEx to DFA Lecture 2 – Implementing Scanners

Eliminating *E*-transitions Lecture 2 – Implementing Scanners

Observation: You never see an epsilon in the input

• Consuming a character means taking a "chain" of zero-or-more ε -edges then a real character edge

Algorithm Intuition: cut out the middleman

• Replace all "chains" with a direct real-character edge

Eliminating *E*-transitions Lecture 2 – Implementing Scanners

- Compute ε-close(s), the set of states reachable via 0 or more ε-edges from s
- Copy all states from N to an ε -free version, N'
- Put s in F' if ε -close(s) contains a state in F
- Put s,c \rightarrow t in δ' if there is a c-edge to t in ε -close(s)

Let ε -close(s) be the set of states reachable via 0 or more ε -edges

Copy all states from N to N'

Put s in F' if ε -close(s) contains a state in F

2

Example, Step IV Eliminating ε -Transitions

Х

 ε -close(S) = {S,1,3,6} ε -close(3) = {3, 6}

- *ɛ*-close(1) = {1}
- *ε*-close(2) = {2}
- *ɛ*-close(4) = {4}
- *ɛ*-close(5) = {5}
- *ɛ*-close(6) = {6}

 ε -close(S) = {S,1,36}

 ε -close(3) = {3, 6}

 ε -close(1) = {1}

ɛ-close(2) = {2}

ɛ-close(4) = {4}

ɛ-close(5) = {5}

ɛ-close(6) = {6}

Note: this definition necessarily preserves all original non- ε edges

Can also remove unreachable "useless" state

Recall: NFA Matching Procedure

Rabin-Scott Powerset construction

- NFA can "choose" which transition to take
 - Always moves to states that leads to acceptance (if possible)
- Simulate set of states the NFA *could* be in
 - If any state in the ending set is final, string accepted

Rabin-Scott Powerset Construction

 $S,x = \{S,A\}$ $A,x = \{R\}$ $R,x = \{D\}$ $D,x = \{\}$ $S,y = \{S\}$ $A,y = \{R\}$ $R,y = \{D\}$ $D,y = \{\}$

Rabin-Scott Powerset Construction

Rabin-Scott Powerset Construction

Rabin-Scott Powerset Construction

 $S,x = \{S,A\}$ $A,x = \{R\}$ $R,x = \{D\}$ $D,x = \{\}$ $S,y = \{S\}$ $A,y = \{R\}$ $R,y = \{D\}$ $D,y = \{\}$

- How may states might the DFA have?
 - 2^{|Q|}
- Why 2^{|Q|}?
 - <u>D</u> <u>S</u> <u>A</u> 0 0 0 {} {D} 0 0 1 0 1 0 {A} {S} 0 0 1 0 1 1
 - 0 1 1 {A,D} 1 1 0 {S,A}
 - 1 0 1 {S,D}
 - 1 1 1 {S,A,D}

From RegEx to DFA Lecture 2 – Implementing Scanners

DONE! ... or are we?

DFA # Tokenizer

- Finite automata only check for language membership of a string (recognition)
- The Scanner needs to
 - Break the input into many different tokens
 - Know what characters comprise the token

- Finite automata only check for language membership of a string (recognition)
- The Scanner needs to
 - Break the input into many different tokens
 - Know what characters comprise the token

We need to go... *beyond recognition*
